1. Introduction

With the development of highly integrated optoelectronic circuits, the feature size of the functional devices such as light-emitting devices, laser, and photodetectors has continued to shrink. Therefore, it is crucial to explore novel materials with readily controlled size, shape, and composition as well as application compatibility in order to lay a solid foundation for the practical applications of the aforementioned devices. For example, the performance of light-emitting devices are predetermined by the active material properties such as band gap energy, exciton binding energy, doping level, metal–semiconductor interfaces, and so on. As for the conventional light-emitting diodes based on the semiconductor films, their performances have been dominated by the rectification characteristics, as an example, the built-in potential and threshold voltage of the devices are determined by the intrinsic doping levels across the junction. Hence, it is difficult to modulate junction properties easily by changing doping concentration and doping profile, because they are mainly limited by the strong screening effect and the increasing 3D density-of-states with increasing energy. Meanwhile, such diodes cannot work under the alternating voltage due to its rectification effect. In addition, the emission wavelengths of the traditional light-emitting diodes are also difficult to adjust due to the band gap of the semiconductor. Albeit recent works have demonstrated the predictability and controllability of emission wavelengths of diodes prepared by chemical or electrochemical doping methods, they usually operate in a liquid environment, which greatly
limits the scope of their applications. Therefore, all-solid-state multicolor visible luminescent devices fabricated by a simple method is still lacking.

Owing to a wide band gap of 3.37 eV and a large exciton binding energy of 60 meV at room temperature, ZnO has received considerable attention as a promising material for optoelectronic devices. In particular, ZnO nano/microstructures are ideal material candidates for many novel applications, such as nanoscale multiplexing biosensors, ultraviolet detectors, and electrically driven lasers. To realize highly efficient optoelectronic devices, enormous efforts have been dedicated to fabricate doped ZnO semiconductor nanostructures with reproducible optical and electronic properties, including the controlled incorporation of n-type and p-type dopants, such as Al, Ga, N, Li, P, and so on. Of all elements, Ga is the most effective n-type dopant in ZnO since the covalent bond length of Ga−O (1.92 Å) is nearly equal to that of Zn−O (1.97 Å). Meanwhile, different growth temperature of ZnO (950 °C) and Ga2O3 (1100 °C) in a vapor–solid progress is conducive to regulating the Ga-doping component. Accordingly, Ga-doped ZnO micro/nanostructures have attracted significant attention due to their notable abilities to give resistance modulation when employed as channel layers of electronic devices. Unfortunately, the tuning range of emission wavelengths is limited for a single micro/nanostructure, which is insufficient for many applications; meanwhile, active tuning of individual tunable emissions. Meanwhile, the temperature-dependent photoluminescence (PL) is also investigated, which indicates that a redshift of the visible emission is achieved upon increasing Ga doping concentration. Therefore, the emitters based on individual ZnO:Ga MWs offer huge advantages over conventional light sources on account of rectification characteristics, consisting of semiconductor nano- and microwires. Furthermore, this type of wavelength-tunable micro/nanoscale emitters are particularly attractive as an indispensable building block for various ultracompact photonic devices.

2. Results and Discussion

In this work, Ga-doped ZnO:Ga microwires (ZnO:Ga MWs) are synthesized by a catalyst-free, vapor-solid process. The effects of Ga doping on the morphologies, optical properties, and the electrical properties of the ZnO microwires are investigated. Electrically driven visible emissions based on individual ZnO:Ga MWs is achieved. Corresponding wavelength tunable electroluminescence (EL) emissions could be certified as a function of the Ga-component in ZnO:Ga MWs. Therefore, to explore the intrinsic physical mechanism of EL emission, electrical breakdown measurement and metal quasiparticle films decorated microwires are carried out. It is found that Joule heating effect plays a key role in the EL emissions. Meanwhile, the temperature-dependent photoluminescence (PL) is also investigated, which indicates that a redshift of the visible emission is achieved upon increasing Ga doping concentration. Therefore, the emitters based on individual ZnO:Ga MWs offer huge advantages over conventional light sources on account of rectification characteristics, consisting of semiconductor nano- and microwires. Furthermore, this type of wavelength-tunable micro/nanoscale emitters are particularly attractive as an indispensable building block for various ultracompact photonic devices.
measurements were performed on both undoped and Ga-doped ZnO MWs to further verify the successful incorporation of Ga dopants into the ZnO crystalline host lattices.

To characterize the optical properties of the ZnO:Ga MWs, room temperature and temperature-dependent PL measurements have been carried out using a He-Cd laser with an excitation wavelength of 325 nm. As shown in Figure 2a, the strong near band emission located around 375 nm can be attributed to the exciton recombination of ZnO through exciton–exciton collision processes for both undoped and Ga-doped ZnO MWs. No defect emission can be observed for undoped ZnO, indicating the good crystallinity and purity, which is consistent with XRD results. Interestingly, a weak visible emission (≈500 nm) can be observed for the four ZnO:Ga MWs samples (Sample-1–Sample-4), which may originate from the intrinsic defects, such as zinc interstitials (Zn_i), zinc antisite (Zn_O), and/or oxygen vacancies (V_O). With increasing Ga-doping amounts, the weak visible emissions change from green (Sample-1) to yellow (Sample-2), orange (Sample-3), and even red (Sample-4). Furthermore, the temperature-dependent PL spectra in the visible range for Sample-2 and Sample-4 are displayed in Figure 2b,c, respectively. For Sample-2, the visible emission peak around 500 nm is attributed to the defect states such as surface defects and oxygen vacancies (V_O). And the emission band obviously redshifted as Ga atoms substitute for Zn sites in ZnO crystalline host lattice, which suggests that the V_O-related defect modes decrease due to Ga-doped effects. For Sample-4, the redshift of the visible emission bands can be obtained as well. As the Ga content increases, the incorporated Ga ions exert a stronger effect on the optical properties of ZnO:Ga MWs in combination with the surface defect modes changing from V_O-related donor levels to complex V_O–Ga related impurity levels, and finally turning into Ga_2O related impurity bands. Thus, the donor density of states can evolve from the discrete level to impurity band. Both the room temperature and temperature-dependent PL results reveal that the visible emission bands of ZnO:Ga MWs shift toward longer wavelengths when increasing Ga-impurities due to the longer bond strength of Ga–O than that of Zn–O.[27,30,36,37,44]

An EL device based on an individual ZnO:Ga MW was constructed with two In electrodes fixed at both ends of microwires. Figure 3a displays schematic illustration of the electrically driven light emission phenomenon from a biased individual ZnO:Ga MW EL device, with light-emitting region toward the center of microwires. In order to examine the Ga-dopant influence on the EL emissions, electrically driven light-emitting devices based on four different ZnO:Ga MWs (Sample-1–Sample-4) were constructed, and the results are presented in Figure 3b. The EL peaks are located around 500 nm for Sample-1, 525 nm for Sample-2, 600 nm for Sample-3, and 638 nm for Sample-4, which suggests that the EL emission of ZnO:Ga MWs can be readily tailored by the Ga-doping amounts. Figure 3c–f displays the digital photographs of the EL emission for Sample-1 (green), Sample-2 (yellow), Sample-3 (orange), and Sample-4 (red), respectively. The light emission is so intense that it is visible by naked eyes (Movie S7 in the Supporting Information).

Electrical measurements of a individual ZnO:Ga MW device were carried out to explore the physical mechanism of EL emission. In order to highlight the EL emission transition from green lighting to red lighting, only the EL characteristics based on Sample-2 and Sample-4 were selected. Current–voltage (I–V) characteristics of Sample-2 and Sample-4 are demonstrated in Figure 4a (electrically driven light emission for Sample-1 and Sample-3 can be referred to Figures S6 and S7 in the Supporting Information, respectively). The linear I–V curves indicate the formation of Ohmic contacts between the In electrodes and ZnO:Ga MWs. The electrical conductivity is even comparable to tungsten lamps. Essentially, the Ga-doping in ZnO is responsible for the excellent conductive capabilities. In addition, the I–V characteristics is independent of the electrode materials (e.g., Au, In) and the injected charged particles. Interestingly, our devices can also work well under alternating current. The EL spectra under different injected direct currents for Sample-2 and Sample-4 are illustrated in Figure 4b,c, respectively. The EL emission wavelengths are red-shifted with the increasing incident current and finally centered at 525 nm by applying a current of 25.6 mA for Sample-2. Similarly, the EL peaks are also redshifted and finally centered at 638 nm by applying
a current of 97 mA for Sample-4. Bright, stable, and localized light emission toward the center of microwires can be observed for both samples as shown in the optical graphs in Figure 4d,e. It is found that the EL emission changes from green to red for Sample-4 when increasing Ga content, which is typically associated with increasing Ga2O3 weight ratio in the source materials.

In addition, a single ZnO:Ga MW with a length $\approx 2$ cm was selected to investigate the relationship between In electrodes and electrical resistances of microwires. A series tandem circuits are formed by dividing the single ZnO:Ga MW into several segments using In electrodes (marked as A, B, C, and D in Figure 5a). The resistances of the segments defined as AB, BC, and CD are calculated to be $R_{AB} \approx 23 \text{ M}\Omega$, $R_{BC} \approx 19 \text{ M}\Omega$, and $R_{CD} \approx 9 \text{ M}\Omega$. The corresponding EL sequence of light emission is: AB segment $\rightarrow$ BC segment $\rightarrow$ CD segment, as demonstrated in Figure 5b (the detailed EL emissions can be referred to Movie S7 in the Supporting Information). Consequently, the segments AB, BC, and CD can be formed to design tandem EL devices. Moreover, electronic resistivity values of ZnO:Ga MWs play a critical role in electrically driven light emission. In order to validate EL emission regions toward the center of the ZnO:Ga MWs, the length of EL devices based on the same MW becomes shorter and shorter by means of In electrodes fixed from one end to the other, as shown in Figure 5c. The EL region shrinks with the shortened wire length, but remains toward the middle site of the active segments (Figure 5d). For the same wire, the longer the length of ZnO:Ga MW, the lower the threshold current for light-emitting, but with little shift the EL emission wavelengths.

To estimate the robustness of ZnO:Ga MWs, instantaneous electrical breakdown measurements were performed.\cite{7,8} Figure 6a displays SEM image of light-emitting device structure with two In electrodes before injecting current. The distinctive ellipse spot along with the length direction of the MW indicates the emission region (Figure 6b). By carefully increasing the incident current that reaches the broken point, instantaneous electrical breakdown of ZnO:Ga MW happens,\cite{7,8,34,35} which leads to the failure of single crystalline ZnO:Ga MW toward the EL emission regions (Figure 6c). Then the ZnO:Ga MW recrystallized from single crystalline to polycrystalline pearl-like structures in the failure process as shown in Figure 6d,e. The discontinuity point (Figure 6f) because of thermionic emission is defined as the broken point and the corresponding current is the broken current. Thus, current heating can be considered as the major factor for failure in the microstructures.\cite{7,8} The electrical breakdown behavior of ZnO:Ga MWs in metal–semiconductor–metal (MSM) structure is related to the Joule Heating effect. If we keep the injected currents, which below the broken current, unchanged for a period, the applied voltage is constant. Stable and reproducible bright visible light emission from ZnO:Ga MWs devices can be acquired. Therefore, electrically driven

**Figure 3.** a) Schematic illustration of electrically injected ZnO:Ga MW showing light-emitting regions toward the center of the MWs. b) Normalized EL intensities for Sample-1, Sample-2, Sample-3, and Sample-4; c–f) Emission photos taken by a digital camera for Sample-1, Sample-2, Sample-3, and Sample-4, respectively, which indicate that the corresponding light-emitting areas are located along the microwire length direction.
light-emitting devices based on individual ZnO:Ga MW is proved to be an effective electrooptical conversion light sources.

Based on the above results, it can be found out that the EL emissions from individual ZnO:Ga MW is associated with Ga-doping concentration and Joule heating effect. To get more insight into the EL mechanism, electrical transport properties of ZnO:Ga MWs in MSM structures were numerically simulated by the thermionic-field-emission model. A single ZnO:Ga MW with diameter $D = 8 \mu m$ and length $L = 5 \mm$ was selected for analysis and modeling. The simulation and analysis of electric potential fields and temperature field distributions have been demonstrated in Figure 7a,b, respectively. The potential field distributes along the length of the microwire from the anode to the cathode under the applied voltage. The temperature field distribution profile illustrates that the hottest spot is always located at the center of the wire, coinciding with the location of the maximum temperature.\[7,8,17\]

For comparative analysis, silver (Ag) quasiparticle nanofilms were evaporated on the ZnO:Ga MWs to figure out the temperature distribution along the wire. Since the emission regions are toward the center of wire (Figure 7c), three regions defined as I, II, and III are selected and their corresponding SEM images are shown in Figure 7d. It is obvious that the Ag quasiparticle film can be converted into isolated large Ag nanospheres ($D \approx 50 \nm$) in the EL emission region (III) due to self-heating effect. By contrast, Ag quasiparticle film was also evaporated on the sapphire substrate, and then subsequently annealed in a N$_2$ atmosphere at 400 °C. It is found that the Ag quasiparticles grow into isolated big Ag nanospheres similarly due to the high temperature annealing as shown in Figure 7e. Therefore, current heating effect instead of thermoluminescence plays a key role in EL emissions. The brightest spot of the emission is always located toward the center of the ZnO:Ga MWs, coinciding with the location of the maximum temperature, which is consistent with the simulation analysis. In such a low current regime, ZnO:Ga MWs used as resistance wires, are largely protect from such undesirable vertical heat dissipation due to Joule heating effect.

The annealing effects of Ag nanoparticles decorated ZnO:Ga MWs emphasize that the recombination of localized electric field can be appeared toward the center of the wires. Therefore, electrons transported in the wire can be accelerated and become energetic electrons. Then the electrons can

be efficiently excited from the valence band (VB) to the conduction band (CB) above the Fermi-level, leaving holes in the VB by means of inelastic collision between ZnO:Ga crystalline host lattices and energetic electrons. Thus, electrons injected into the CB are accelerated by the large potential difference. The accelerated electrons may produce excitons by impact excitation, which can decay radiatively. Owing to the localized electric field rearrangement, EL spectra can be recorded as a function of injected currents. The combination of recombinated localized electric field in ZnO:Ga MWs provides a channel to study the interaction of hot electrons being accelerated by localized electric field and electrons situated at crystalline host lattices.\[37,43\]

Schematic diagram of electrically injected luminescence dynamics process by means of the inelastic collision between ZnO:Ga crystalline host lattices and electrons is presented in Figure 8a, which indicates high kinetic energy derived from the rearrangement of the localized electric field acceleration. The brilliant fireballs are defined as hot electrons being accelerated by localized electric field, and they collide with ZnO:Ga crystalline host lattices by steady inelastic collision. The inelastic scattering of the primary electrons in the crystal leads to the emission of secondary electrons, Auger electrons, and X-rays, which in turn can scatter as well.\[7,16\] Electrons can be motivated and transited

to CB, thereby forming electron–hole (e–h) pairs. Then, non-equilibrium electrons in the CB energy levels after relaxation and transition to impurity bands, therefore, radiative recombination can occur between electrons occupied at impurity band and holes at VB. To confirm the electrically driven light-emitting physical mechanism, the resistances and the biased voltages were taken into account. Take Sample-2 for example (Figure 8b), once the biased voltage exceeds 5 V, the changes are incompatible with the undoped ZnO MWs due to Joule heating effect. The thermal conductivity of ZnO:Ga MWs at high lattice temperatures (heated due to Joule heating effect) is greatly reduced, which also suppresses lateral heat dissipation. In consequence, recombination of localized electric field toward the center of the wire is formed, that is also why hot electrons become spatially localized at the center of the wire, causing greatly increase of the efficiency and brightness of the light emission. In addition, defect spectroscopy of single ZnO MWs has been indicated that there is a characteristic deep defect levels inside the gap at 0.88 eV from the top of the VB, and a defect level next to the bottom of the CB at 0.11 eV (Figure S5, Supporting Information). The presence of these defect levels attribute to Zn\(\mathrm{Zn}^{2+}\) and V\(\mathrm{Zn}^{-}\), respectively.\(^{35,36}\) Moreover, it has been verified that the oxygen vacancies are the dominant acceptor defects in as-grown ZnO MWs. In the typical synthesis process with a hypoxia environment, lattice expansion exists due to the substitution of Ga for Zn. Therefore, the EL peak around 500 nm under low current injection can be attributed to the recombination of electrons located in the VO related defect level (the green band) and holes located in the V\(\mathrm{Zn}^{-}\) related defect level (light blue band) (Figure S5, Supporting Information). When increasing the Ga-content in ZnO:Ga MWs, oxygen vacancy related defect modes will become important. Instead, Ga\(\mathrm{Zn}\) related defect modes will gradually form a new donor level, or even Ga\(\mathrm{Zn}\) related impurity band. The process changing from VO related defect modes to Ga\(\mathrm{Zn}\) related impurity band is a pathophysiological course, accompanied by the donor density of states evolving from the discrete level to impurity band and eventually to band tail. In consequence, increasing doping concentration, the wavefunctions of the donors will overlap and result in the formation of an impurity band as shown in Figure 8c. The band broadens with further increase of the doping and eventually merges with the CB, forming a band tail. In this case, the PL and EL occur from the band tail to the VB or acceptor-like states.

According to the literature, the electrically driven light emission from a single semiconductor component (micro/nanostructure) can be explained by several different scenarios:\(^{10}\) a bipolar EL mechanism where the electrons and holes are injected simultaneously into the structures, such as EL emissions from p–n, p–i–n junction;\(^{1,2}\) a unipolar impact excitation process by hot carriers (e.g., metal–semiconductor based Schottky junction);\(^{9,10}\) and thermal light emission due to Joule heating effect (e.g., graphene).\(^{120}\)
For Ga-doped MWs that are treated as metallic wires, once the biased voltage reaches a certain value, the resistances increase exponentially, which helps to explain the change in electron movements during the transport process. The EL spot and electrically injected breakdown behavior can be well explained by Joule heating mechanism. Nevertheless, thermal heating can also be ruled out as a source by the experimental observations, such as increasing the injected current brings redshift of the EL, increasing Ga-doping concentration in ZnO MWs brings redshift of the EL in the visible bands, together with the enhanced EL under low-temperature environment. Therefore, the electrically injected light-emitting mechanism of ZnO:Ga MWs may provide another electrically driven light emission as following: (1) Rearrangement of localized electric field can be formed toward to the center of ZnO:Ga MWs, so accelerated electrons become spatially localized toward the center and inelastic collision with ZnO host lattices; (2) An impact excitation process under electrical transport can generate an abrupt potential drop and a strong electric field due to Joule heating, and the carriers are accelerated to scatter inelastically and produce electron–hole pairs, then the EL emission can occur through the radiative electron–hole recombination; and (3) Different complex defect levels due to the Ga-impurity content in ZnO:Ga MWs can be used to adjust the EL emission wavelengths.

It can be found that Ga dopant acted as electrical dopants can be used to increase n-type electron concentration of ZnO MWs, as well as improving corresponding electric conductivity. Under an external electrical field, collision ionization interactions between injected carriers and crystal host lattice of ZnO:Ga MWs can occur. Due to the single-crystallinity, heat transport induced by Joule heating effect is greatly reduced. Then hot carriers can be formed by means of the Joule heating effect, therefore become spatially localized toward the middle segment of ZnO:Ga MWs. Meanwhile, this kind of high-energy particles can motivate the transition of electrons from the VB to the CB, thereby forming the nonequilibrium states of hot electrons. Therefore, the light emission can be attributed to the radiative recombination between the electrons situated at impurity bands and the holes situated at the valence band, respectively.

3. Conclusion

In summary, ZnO:Ga MWs with good single-crystalline structures have been successfully synthesized via a one-step CVD process. The Ga-impurity doping is found to improve electrical conductivities of the ZnO microwires, which could be treated as metallic wires. Owing to the fantastic electronic transport properties and the tunable PL wavelengths in the visible range, individual ZnO:Ga MWs based EL devices can serve as electrically driven light-emitting sources with different colors, which is analogous to the incandescent light. In particular, increasing the Ga-doping concentration leads to redshift of the EL emission peaks in the visible range. The EL emission region is localized toward the center of MWs, no matter how the electrode configurations and the distance between two In electrodes change. Electrical breakdown measurement results indicate that Joule heating effects play crucial roles in the lighting phenomenon. Interestingly, the individual ZnO:Ga MW-based EL devices can also function well under alternating current. The EL emitters prepared in this study provide a versatile route to combine the active functionality of the incandescent sources for future optoelectronic devices.
4. Experimental Section

**Preparation of ZnO:Ga MWs:** The ZnO:Ga MWs were synthesized on a silicon substrate via a traditional chemical vapor deposition method in a horizontal tube furnace. In a typical process, a mixture of ZnO, Ga₂O₃, and graphite powders with a definite weight ratio of 9:1:10 was served as the reactive sources. Cleaned Si (100) substrates (without any catalyst coating) were placed on the ceramic boat to collect the products. The growth temperature was kept at 1120 °C for 45 min.[27,30,43] During the synthesis process, a constant flow of argon (99.99%) (120 standard cubic centimeters per minute) was introduced into the tube furnace. In addition, to investigate different Ga content in ZnO:Ga MWs, four different weight ratio of the reactive sources of ZnO: Ga₂O₃: graphite powders, such as 10:1:11 (Sample-1), 9:1:10 (Sample-2), 8:1:9 (Sample-3), and 5:1:6 (Sample-4) were prepared.

**Device Fabrication:** Quartz substrates were cut into pieces of 3 cm × 2 cm, and ultrasonically cleaned successively in acetone, ethanol, and deionized water for 15 min. Subsequently, a single ZnO:Ga microwire was selected to transfer onto the quartz substrate. Two indium (In) particles were fixed on the both ends of the ZnO:Ga MWs by annealing for 2 min at 200 °C. Two InO:Ga MWs were fixed on the substrate to give a MSM structure-based EL device.

**Analysis Instruments:** SEM images were recorded using a Hitachi S-3000N/S-4800. XRD θ–2θ scans were carried out by employing a Rigaku X-ray diffractometer. XPS were taken for the high-resolution analysis of Zn, Ga, and O atoms. The binding energies were calibrated with respect to the C 1s peak at 284.8 eV. The backscattering geometry configuration was used to obtain the emission wavelength at 325 nm, and a micro-Raman spectrometer in a reflection method in a horizontal tube furnace. In a typical process, a constant flow of argon (99.99%) (120 standard cubic centimeters per minute) was introduced into the tube furnace. During the synthesis process, a constant flow of argon (99.99%) (120 standard cubic centimeters per minute) was introduced into the tube furnace.
